Drug-induced liver injury is an uncommon but challenging clinical problem with respect to both diagnosis and management. Its incidence is estimated to be 14 to 19 cases per 100,000 persons, with jaundice accompanying 30% of cases. Drug-induced liver injury is responsible for 3 to 5% of hospital admissions for jaundice and is the most frequent cause of acute liver failure in most Western countries, accounting for more than half of cases. Advances have been made in our understanding of viral, autoimmune, and genetic liver diseases, as well as approaches to their prevention and treatment, but progress on these fronts has been modest in the case of drug-induced liver injury.

The diagnosis of drug-induced liver injury is particularly challenging, since it is based largely on exclusion of other causes. The timing of the onset of injury after the implicated agent has been started (latency), resolution after the agent is stopped (“dechallenge”), recurrence on re-exposure (rechallenge), knowledge of the agent’s potential for hepatotoxicity (likelihood), and clinical features (phenotype) are the major diagnostic elements. With few exceptions, there are no specific diagnostic markers for drug-induced liver injury, and special tests (liver biopsy, imaging, and testing for serologic markers) are helpful mostly in ruling out other causes of liver injury. The large number of agents that can cause liver injury highlights these challenges. LiverTox, the National Institutes of Health–sponsored website on hepatotoxicity, has descriptions of more than 1200 agents (prescription and over-the-counter medications, herbal products, nutritional supplements, metals, and toxins), along with their potential to cause liver injury. Among the 971 prescription drugs described, 447 (46%) have been implicated in causing liver injury in at least one published case report. This brief review cannot cover all aspects of drug-induced liver injury but focuses on general principles, newer concepts, and current challenges, with frequent references to the LiverTox website for further detail.

Types of Drug-Induced Liver Injury

Drug-induced liver injury is typically classified as either direct or idiosyncratic, but indirect injury is emerging as a third type (Table 1). Direct hepatotoxicity is caused by agents that are intrinsically toxic to the liver. The injury is common, predictable, dose-dependent, and reproducible in animal models. The latency period is typically short, usually with an onset within 1 to 5 days after high therapeutic or supratherapeutic doses, as in the case of an intentional or accidental overdose.

Idiosyncratic hepatotoxicity is caused by agents that have little or no intrinsic toxicity and that cause liver injury only in rare cases, typically after 1 in 2000 to 1 in 100,000 patient-exposures. The injury is unpredictable, not dose-dependent, and not reproducible in animal models. Idiosyncratic liver injury is categorized as hepatocellular, cholestatic, or both (mixed) on the basis of the R ratio, calculated by...
dividing the alanine aminotransferase level by the alkaline phosphatase level from the time of initial presentation, with both values expressed as multiples of the upper limit of the normal range. Hepatocellular injury is defined as an R value of more than 5, cholestatic injury as a value of less than 2, and mixed injury as a value of 2 to 5.

Indirect hepatotoxicity is caused by the action of the drug (what it does) rather than by its toxic or idiosyncratic properties (what it is). Indirect injury can represent induction of a new liver condition or an exacerbation of a preexisting condition, such as induction of immune-mediated hepatitis or worsening of hepatitis B or C or fatty liver disease.

### Major Phenotypes
The three types of drug-induced liver injury are manifested by distinctly different patterns of clinical features (phenotypes) (Table 2).

#### Direct Hepatotoxicity
Serum enzyme elevations without jaundice constitute the most common pattern of direct drug-induced liver injury, with elevations of alanine aminotransferase or alkaline phosphatase levels but without hyperbilirubinemia and with minimal or no symptoms. The elevations resolve when the drug is stopped or the dose is lowered but can also resolve spontaneously, a phenomenon referred to as adaptation. In some cases, adaptation does not occur, and enzyme elevations worsen and jaundice and symptoms arise. The mechanism or mechanisms underlying adaptation are unknown but may result from changes in drug-metabolizing enzyme activity, up-regulation of hepatoprotective pathways, or down-regulation of hypersensitivity reactions to the drug or its metabolites.

Acute hepatic necrosis is the most common form of clinically apparent direct hepatotoxicity. The injury occurs abruptly, soon after the medication has been started, often after exposure to a single high dose or a dose increase (Fig. 1A). Serum alanine aminotransferase levels rise to high values, whereas alkaline phosphatase levels are minimally elevated. In severe cases, signs of hepatic failure such as coagulopathy, hyperammonemia, or coma arise within days. Liver histologic studies show centrilobular or panlobular necrosis with little inflammation, a pattern similar to that of ischemic hepatitis, the major disorder in the differential diagnosis. Acute hepatic necrosis can be fatal, but if it is not, recovery is rapid, and serum enzyme levels fall almost as rapidly as they rose. High doses of acetaminophen, aspirin, niacin, amiodarone, IV methotrexate, cancer chemotherapy, amoxicillin-clavulanate, cephalosporins, isoniazid, nitrofurantoïn, minocycline, fluoroquinolones, macrolide antibiotics, and antineoplastic agents, glucocorticoids, monoclonal antibodies (against tumor necrosis factor, CD20, checkpoint proteins), protein kinase inhibitors can cause acute hepatic necrosis. Typically, these drugs can be restarted at lower doses without a recurrence of injury. Poisonous mushrooms (Amanita phalloides) and other environmental toxins can cause a similar syndrome of acute hepatic necrosis.

Sinusoidal obstruction syndrome, previously known as veno-occlusive disease, is due to acute injury and loss of intrasinusoidal endothelial cells, resulting in obstruction of sinusoidal blood flow and liver injury.21,22 Drugs are the usual cause, the most common being myeloablative agents administered in preparation for hematopoietic cell transplantation. Symptoms of abdominal pain, increase in liver size, and weight gain, followed by jaundice, appear 1 to 3 weeks after exposure and may progress rapidly to hepatic failure. Liver histologic studies show dilatation of sinusoids and extravasation of red cells, with hepatocyte necrosis in central areas (zone 3).22 Drugs that cause sinusoidal obstruction syndrome include alkylating agents such as busulfan or cyclophosphamide and monoclonal antibody–cytotoxic conjugates such as gemtuzumab ozogamicin.23 The syndrome can also be caused by botanicals (pyrrolizidine alkaloids).24 Defibrotide, an antithrombotic agent, has recently been approved as therapy for severe sinusoidal obstruction syndrome with organ failure, but its use is controversial.24

Nodular regenerative hyperplasia is usually manifested as unexplained, noncirrhotic portal hypertension with esophageal varices or ascites. Nodular regeneration can be caused by cancer chemotherapeutic agents given over a long period or in multiple courses (azathioprine, mercaptopurine, or thioguanine)25 or by first-generation nucleoside antiretroviral agents (zidovudine, stavudine, or didanosine).26 Nodular regenerative hyperplasia with resultant portal hypertension has also been linked to oxaliplatin infusions for metastatic colon cancer.27 The pathogenesis of nodular regeneration is unclear, but it may be the result of chronic injury to the hepatic microvasculature. Management should include withdrawal of the medication (and avoidance of similar agents) and treatment of portal hypertension.

Lactic acidosis with microvesicular steatosis and hepatic dysfunction typically occurs with nonspecific symptoms of abdominal discomfort,
Drug-Induced Liver Injury

fatigue, and weakness, with subsequent confusion, stupor, and coma accompanied by liver injury. Lactic acidosis or hyperammonemia may be prominent. Jaundice arises late, and enzyme elevations are variable, sometimes markedly hepaticellular (with Reye's syndrome triggered by

Figure 1. Common Phenotypes of Drug-Induced Liver Injury.
Panel A shows an example of acute hepatic necrosis and direct liver injury. A 48-year-old woman with valvular heart disease had marked alanine aminotransferase (ALT) elevations with jaundice but no increase in alkaline phosphatase (Alk P) levels, within a day after starting to receive intravenous amiodarone (300-mg bolus followed by 900 mg daily). The abnormalities reversed rapidly on withdrawal of the medication. She later received oral amiodarone without recurrence of the liver injury. Panel B shows an example of idiosyncratic acute hepatocellular hepatitis. A 77-year-old woman presented with jaundice 36 days after starting diclofenac (75 mg twice daily) for osteoarthritis, with marked ALT but minimal Alk P elevations, profound jaundice, transient signs of liver failure, and subsequent spontaneous but slow resolution. Panel C shows an example of idiosyncratic cholestatic hepatitis. Itching and jaundice developed in a 68-year-old man a week after he received a single intravenous infusion of cefazolin (1 g) during outpatient orthopedic surgery. He had prominent Alk P elevations but modest ALT elevations, which resolved within a few weeks after their onset. Panel D shows an example of bland cholestasis. Jaundice developed in a 39-year-old man approximately 3 months after he started a bodybuilding regimen that included daily doses of an oral anabolic steroid, with modest ALT and Alk P elevations, despite marked and prolonged itching and hyperbilirubinemia. For all four cases, the test results are given as multiples of the locally defined upper limit of the normal range (ULN), except in the case of bilirubin, for which the ULN was set at 1.0 mg per deciliter (17.1 μmol per liter).
aspirin)\textsuperscript{32} and sometimes with milder, mixed patterns. The time to onset can be days (with aspirin or intravenous tetracycline),\textsuperscript{30} weeks (with linezolid),\textsuperscript{11} or months (with didanosine).\textsuperscript{28,32} Liver biopsy shows microvesicular steatosis with minimal inflammation and necrosis. The pathogenesis of the injury is mitochondrial toxicity and failure of aerobic metabolism. Similar injury in other tissues may accompany and overshadow the liver injury (neuropathy, myopathy, and pancreatitis). Therapy should focus on withdrawal of the responsible agent, administration of glucose infusions, and correction of acidosis.\textsuperscript{28}

**IDIOSYNCRATIC HEPATOTOXICITY**

Acute hepatocellular hepatitis is the most common manifestation of idiosyncratic liver injury.\textsuperscript{5,13,33} The latency period generally ranges from 5 to 90 days. The symptoms and course resemble those of acute viral hepatitis, with prominent alanine aminotransferase elevations (increased by a factor of 5 to 50), whereas alkaline phosphatase levels are only modestly increased (Fig. 1B). Liver histologic studies show changes suggestive of acute viral hepatitis, the major disorder in the differential diagnosis, but eosinophils may be prominent. The rate of death from icteric hepatocellular injury due to medications is high, usually 10% or higher, a feature first stressed by the late Hyman J. Zimmerman, for which reason it is called Hy’s law.\textsuperscript{1,34} A key feature of Hy’s law is jaundice with hepatocellular rather than cholestatic injury. Drug-induced idiosyncratic acute hepatocellular injury is an important cause of acute liver failure, accounting for 11 to 15% of cases in series from the United States and Europe.\textsuperscript{28} Common causes of drug-induced idiosyncratic acute hepatocellular injury are isoniazid, nitrofurantoin, and diclofenac.\textsuperscript{13,16,33,35}

Chronic hepatitis is an uncommon form of drug-induced liver injury; the chronicity occurs if the agent is continued and typically resolves slowly once the agent has been stopped. Many agents that cause acute hepatocellular injury can also cause a chronic hepatocellular pattern.\textsuperscript{1,35} The injury arises after months or years of exposure. Autoantibodies are frequently present, and the differential diagnosis often focuses on ruling out spontaneous autoimmune hepatitis. Common causes of drug-induced, autoimmune-like chronic liver injury are nitrofurantoin, minocycline, hydralazine, methyl dopa, statins, and fenofibrate.\textsuperscript{16,35-38} Glucocorticoids, which are frequently used to manage chronic hepatitis (starting dose, 20 to 60 mg of prednisone or its equivalent daily), may alleviate symptoms and speed recovery, but the injury will often resolve without intervention. If prednisone is used, the dose and duration should be kept to a minimum. Monitoring for evidence of relapse should be performed for at least 6 months after the withdrawal of glucocorticoids. Ultimately, spontaneous autoimmune hepatitis is best ruled out by evidence of resolution of the liver injury after withdrawal of the medication and, if glucocorticoids are used, by the absence of relapse when they are discontinued.\textsuperscript{36}

Cholestatic hepatitis is characterized by prominent symptoms of pruritus and jaundice accompanied by moderate-to-marked elevations in alkaline phosphatase levels (Fig. 1C). Drug-induced cholestatic liver injury is usually self-limited, and although often protracted, it ultimately resolves.\textsuperscript{13,39} Liver histologic studies show bile duct injury and cholestasis in small bile canaliculi.\textsuperscript{40} Exceptions to the usual benign course occur when there is bile duct loss, which is associated with delayed resolution of jaundice and elevated enzyme levels.\textsuperscript{41} Some cases evolve into vanishing bile duct syndrome, with prolonged jaundice, liver failure, need for liver transplantation, or death. Common causes of drug-induced cholestatic hepatitis are amoxicillin–clavulanate, cephalosporins, terbinafine, azathioprine, and temozolomide.\textsuperscript{13,38,42-44}

Drug-induced mixed hepatitis is caused by many agents, some of which also cause hepatocellular or cholestatic hepatitis.\textsuperscript{13,33} The mixed forms of drug-induced liver injury tend to have the most benign outcomes, rarely leading to liver failure. Common causes of drug-induced mixed hepatitis include the fluoroquinolone and macrolide antibiotics, phenytoin, and sulfonamides.\textsuperscript{13,45,46}

All forms of idiosyncratic drug-induced hepatitis can be accompanied by immunologic features, such as rash, fever, and eosinophilia — signs of drug hypersensitivity.\textsuperscript{13,34,47} More extreme examples include drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome, toxic epidermal necrolysis, and the Stevens–Johnson syndrome.\textsuperscript{48,49} Prominent causes of idiosyncratic drug-induced hepatitis with immunologic features include allopurinol, carbamazepine, phenytoin, sulfonamides, and macrolide antibiotics.\textsuperscript{46-49} Immunoallergic hepatitis is more common among black Americans than among non-Hispanic white Americans.\textsuperscript{50}
Bland cholestasis represents a distinctive phenotype of drug-induced liver injury, characterized by marked and prolonged jaundice with pruritus. In women, bland cholestasis is typically caused by estrogens or oral contraceptives, and in men it is typically caused by anabolic steroids, usually obtained illicitly for bodybuilding or improving athletic performance. Jaundice and pruritus arise within 30 to 90 days, and elevations in enzyme levels are minimal or modest, despite marked and prolonged jaundice (Fig. 1D). Liver biopsy shows bland cholestasis with scant inflammation and hepatocellular necrosis. The cholestasis can be prolonged, but the injury is almost always self-limited and deaths are rare. The pathogenesis remains unclear.

INDIRECT HEPATOTOXICITY

Indirect drug-induced liver injury results from the medication’s actions rather than from its inherent hepatotoxic effects or immunogenicity; the injury represents induction or exacerbation of a liver disease. The phenotypes are those of the underlying disease or predisposition. Fatty liver disease can be an indirect effect of drugs that cause weight gain (risperidone and haloperidol) or that alter triglyceride disposition (lomitapide) or insulin sensitivity (glucocorticoids). Acute hepatitis can be the indirect effect of anticancer chemotherapeutic agents that cause a reactivation of hepatitis B or of antiretroviral agents that cause immune reconstitution and exacerbation of hepatitis C. An increasingly common form of indirect injury is immune-mediated liver injury due to various immunomodulatory agents, tumor necrosis factor antagonists, and most dramatically, antineoplastic checkpoint inhibitors. Many of these agents are monoclonal antibodies and are thus unlikely to cause direct or idiosyncratic liver injury. Hepatocellular or mixed hepatitis with immune features usually arises within 2 to 12 weeks after the start of therapy (or after one to three courses) and is often detected during routine monitoring at the time of each infusion. Many cases are anicteric and asymptomatic, but without intervention, the hepatitis can worsen and become life-threatening. Therapy with glucocorticoids is usually recommended. If the injury resolves promptly, the agent can be restarted or another agent can be substituted (infliximab can be switched to etanercept, or ipilimumab to nivolumab).

Indirect liver injury is a new and not completely accepted category of hepatotoxicity. Nevertheless, the clinical features are distinct (Table 1). Indirect injury is much more frequent than idiosyncratic forms and is a common reaction to a whole class of medications (e.g., tumor necrosis factor antagonists and checkpoint inhibitors) rather than a rare and idiosyncratic reaction to a random, specific agent (e.g., nitrofurantoin or atorvastatin). Indirect drug-induced liver injury represents an expanded concept of hepatotoxicity and provides insights into liver conditions that are worsened (e.g., the types of immunomodulation that cause reactivation of hepatitis B) or into predispositions to liver conditions. There are plausible explanations for the pathogenesis of indirect injury, and in most instances, this type of drug-induced liver injury can be prevented or treated.

CURRENT MAJOR CAUSES OF DRUG-INDUCED LIVER INJURY

The current major causes of clinically apparent liver injury due to prescription drugs are shown in Table 3. These data are based on more than 1000 cases of suspected idiosyncratic drug-induced liver injury seen at five to eight medical centers across the United States between 2004 and 2013. All cases were formally adjudicated, and the implicated agent was classified as the definite, highly likely, or probable cause. The most commonly implicated agents were amoxicillin–clavulanate, isoniazid, nitrofurantoin, tri methoprim–sulfamethoxazole, and minocycline. These medications might be the most common causes of idiosyncratic drug-induced liver injury, but liver injury in persons taking these drugs is rare. Inclusion in the top 25 implicated agents reflects not just the hepatotoxicity potential but also how commonly the drugs are used and the duration of treatment, which can range from a single intravenous infusion (cefa zolin), to a 3-to-14-day course (oral antibiotics), to a year or more of therapy (nitrofurantoin, minocycline, and atorvastatin). The actual incidence of idiosyncratic liver injury from specific drugs is difficult to define; estimates include 1 case per 1000 exposures (isoniazid), 1 per 2500 (amoxicillin–clavulanate), 1 per 10,000 (diclofenac), 1 per 20,000 (atorvastatin), and 1 per 50,000 or more (most drugs). Host and environmental factors may affect the risk, but risk factors are not well de
fined and are probably specific to the agent, such as male sex and older age for amoxicillin–clavulanate,39 alcoholism for isoniazid,12 and African ancestry for phenytoin, allopurinol, and trimethoprim–sulfamethoxazole.48,50 Furthermore, there is little evidence that particular combinations of agents are more likely to lead to idiosyncratic hepatic injury, although combinations of hepatotoxins are fairly clear risk factors for direct injury.

A striking finding is that 9 of the top 10 causes of drug-induced liver injury are antimicrobial agents, largely antibiotics. In addition, most of the drugs have been in widespread use for decades. Among the 25 most commonly implicated agents, only 3 were introduced after 2000 (rosuvastatin [2003], duloxetine [2004], and telithromycin [2004]). The reasons that more recently approved drugs are less likely to be implicated in liver injury are not clear but may reflect improvements in drug design, preclinical screening for toxic effects, and a focus on agents with better safety profiles (those that are given in lower doses, are less likely to affect hepatic metabolism, are less lipophilic, and are less likely to interact with other drugs).2,63,64 Another possible reason is the increased scrutiny and criteria for proof of safety required by the Food and Drug Administration.34,65

Although recently approved agents may have fewer hepatotoxic effects, many are still of concern. Of note are the kinase and other targeted enzyme inhibitors, more than 50 of which have been introduced in the past two decades.12 Most are antineoplastic agents that cause transient elevations in serum enzyme levels in a sizable proportion of patients and more rarely cause icteric, clinically apparent liver injury (e.g., imatinib, nilotinib, bortezomib, pazopanib, and ribociclib).60 Also notable are monoclonal antibodies, more than 70 of which are now available. Although these agents are frequently used for cancer chemotherapy, their use has expanded to encompass the treatment of nonmalignant conditions such as autoimmune diseases, migraines, and hypercholesterolemia, as well as management after organ transplantation. Most monoclonal antibodies do not cause liver injury, the exception being those with immunomodulatory actions.

* Data are from Chalasani et al.13 The listed agents are those most frequently implicated in a total of 1257 cases of drug-induced liver injury reported between 2004 and 2013; agents were classified as definite, highly likely, or probable causes (in 899 cases). Agents that ranked from 14th to 25th in frequency were hydralazine, lamotrigine, and mercaptopurine (9 cases each); atorvastatin and moxifloxacin (8 cases each); and allopurinol, amoxicillin, duloxetine, rosuvastatin, telithromycin, terbinafine, and valproic acid (7 cases each). FDA denotes Food and Drug Administration.
† The percentages have been calculated on the basis of a total of 899 cases of drug-induced liver injury.
plexing problem. In studies from the United States, the proportions of cases of liver injury caused by herbal or dietary supplements increased from 7 to 9% in 2004–2007 to 19 to 20% in 2010–2014.66,67 This change probably reflects the increasing use of herbal products and dietary supplements, as well as the lack of rigorous regulatory oversight in the preparation and marketing of these products. The specific products implicated are generally not single herbs (aloe vera, saw palmetto, or black cohosh) or single nutritional substances (creatine, omega fatty acids, or vitamins) but rather are typically multiple-ingredient dietary supplements marketed for weight loss, bodybuilding, or improvements in sexual function, general well-being, or mental acuity.67 These products often have 5 to 20 ingredients, including vitamins, minerals, proteins, and herbs or botanicals of uncertain quality and concentration, often referred to as a “proprietary blend.” The specific chemical component (or components) responsible for the liver injury is rarely obvious. Most multiple-ingredient dietary supplements have commercial names, which are linked to no more than one or two cases of liver injury. Some, however, have been implicated in outbreaks (e.g., HydroxyCut and OxyELITE Pro). Once a popular proprietary supplement is implicated in liver injury, the manufacturer may alter the ingredients and continue to market the product under the same name.

Strikingly, the clinical phenotype of liver injury in most cases associated with herbal and dietary supplements is acute hepatocellular hepatitis, which is often severe, with a high rate of fulminant hepatic failure and need for liver transplantation.66 Commonly implicated components are green tea extracts (Camellia sinensis). The suspected active molecular constituents are catechins, which at high doses cause liver injury in animal models.66-68 The concentrations of green tea in the animal models, however, are much higher than those in commercial supplements implicated in causing injury in humans.69 In a placebo-controlled trial of green tea extract for the prevention of breast cancer, elevations in serum alanine aminotransferase levels occurred in 6.7% of recipients (36 of 538), as compared with 0.7% of controls (4 of 537).70 The abnormalities were asymptomatic and resolved promptly with discontinuation of the supplement but recurred rapidly on readministration, suggesting that the injury was idiosyncratic and probably immune-mediated.

The pathogenesis of direct and indirect hepatotoxicity is reasonably well understood, whereas that of idiosyncratic injury is not. Genomewide association studies of large numbers of idiosyncratic cases have identified several genetic associations, most within the major histocompatibility complex (MHC) region and linked to HLA class I and II alleles. In general, the HLA associations were to uncommon alleles and were specific to selected agents, such as HLA-B*57:01 for fluclucosinill,71 HLA-A*02:01 and HLA-DRB1*15:01 for amoxicillin–clavulanate,72 and HLA-A*33:01 for fenofibrate and terbinafine.78,82 These associations were not reliable enough to warrant screening for HLA alleles in selecting medications, but they suggest an immunologic pathogenesis. This hypothesis is supported by the observation that implicated drugs or their metabolites bind to the active T-cell receptor groove dictated by the HLA association.73

More recently, genomewide association studies have identified a risk allele for idiosyncratic drug-induced liver injury outside the HLA region that is linked to a missense mutation in an immunomodulatory gene encoding PTPN22,74 a protein tyrosine phosphatase that acts by down-regulating T-cell receptor signaling.75 The same missense mutation (c.C1858T, p.R620W) has also been linked to an increased risk of autoimmune diseases. This allele appears to be linked to multiple forms of idiosyncratic drug-induced liver injury.

An attractive hypothesis is that idiosyncratic drug-induced liver injury is due to a perfect storm of events, each of which is required for full expression of the injury. The production of an abnormal metabolite of the drug by the liver is followed by mild liver-cell injury and then by an immunologic response to the metabolite presented on the injured hepatocyte surface to a specific HLA-restricted T-cell receptor.73 Without adaptation, the immune recognition triggers further T-cell activation, cytokine release, and hepatocyte injury. This hypothesis may ultimately help to improve the identification of safer drugs in development.

Drug-induced liver injury is an uncommon but clinically important form of liver disease, its frequency driven by how often drugs are taken and
the likelihood that they cause injury. The multiple types and phenotypes of injury vary according to the agent, presenting a diagnostic challenge. Recognizing phenotypes of drug-induced liver injury is helpful in establishing the diagnosis, identifying the responsible agent, and providing insights into pathogenesis. A better understanding of the pathogenesis of drug-induced liver injury should allow for better diagnostics and, ultimately, improved approaches to prevention and treatment.
